Enhanced oxidation power in photoelectrocatalysis based on a micrometer-localized positive potential in a terrace hetero p – n junction

Mohd Fairus Ahmad^{1,2}, Motoya Suzuki¹, Toshiyuki Abe³ and Keiji Nagai¹

Abstract

Generally, p – n junction-based solar energy conversion has the disadvantage of a loss in potential gain in comparison with the photon energy. In this study, we found a more positive potential for a lateral domain interface of p – n junction than for a conventional p – n junction. A terrace bilayer (TB) p – n junction of phthalocyanine (H_2Pc) and 3,4,9,10-perylenetetracarboxylic-bis-benzimidazole (PTCBI) was studied using scanning Kelvin probe microscopy (SKPM), and its electronic properties were analyzed using the contact potential difference (V_{CPD}) data. The analysis of V_{CPD} in the single layer region and the bilayer region (BLR) indicated a vacuum level shift through the electron transfer from PTCBI into indium tin oxide (ITO), from H_2Pc into ITO and from H_2Pc into PTCBI. Furthermore, the comparison of these V_{CPD} data indicated a micrometer-localized positive potential in the boundary region (BDR) of the terrace bilayer structure of p -type on n -type. The gain difference of the V_{CPD} reached +0.1 V in comparison with the BLR. The phenomena can be explained as a lateral dipole at the p – n junction. Similar phenomena were observed in TB- $H_2Pc/C_{60}/ITO$ and TB- $H_2Pc/PTCBI/Au$. The gain was extracted as oxidation power in photoelectrochemistry; i.e., at -0.2 V vs. Ag/AgCl a greater anodic current was observed for a patterned terrace bilayer electrode. Additionally, as a photocatalyst film (i.e., a H_2Pc (dot)/PTCBI/PTFE membrane filter), the p – n dot terrace structure showed a higher quantum efficiency (5.1%) than that of the bilayer (3.2%) for the decomposition of acetic acid. The present design and method were utilized to obtain an efficient photocatalyst, especially through the mitigation of potential loss from the photon energy to redox powers without changing the molecular component.

Introduction

Organic semiconductor materials (OSMs) have been studied for many photovoltaic applications, such as solar cells^{1–12}, through the design and synthesis of new molecules, morphology control^{1–12}, and extension to photocatalysts^{13–19}. The Fermi level (E_F) of an OSM is useful for analyzing its characteristics, such as band bending and

transport performance^{20–38}. Scanning Kelvin probe microscopy (SKPM) as a surface potential analysis method is a technique for analyzing the Fermi level of an OSM and strongly affects its photogenerated carriers and open circuit voltage (V_{OC}). The SKPM technique can obtain quantitative information about an OSM without high energy photon or vacuum conditions.

In photovoltaic applications, the OSM heterojunction structure has been commonly used to maximize the carrier generation performance during photoirradiation. A disadvantage of p – n junctions is the drastic loss of the exciton energy compared to the energy difference between the edges of the n -type conduction band and the

p-type valence band. Although the levels can be tuned by molecular design and synthesis, there is a trade-off relation with a large band gap as well as light absorption of high energy photons. To focus on the charge separation site, the *p*–*n* junction interface, we utilize SKPM. Most past research on bulk heterojunctions (BHJs), the morphologies of *p*-type and *n*-type domains, and their interphases focused on investigating the performance of the photovoltaics. Using conductive atomic force microscopy (CAFM), Coffey et al. mapped the morphological photocurrents with a 20 nm resolution for the BHJ of MDMO-PPV:PCBM and discussed the significant variation of the short-circuit current, which depended on the local mobility difference due to the BHJ²⁰. Using SKPM, Chiesa et al. discussed the surface potential variation not only for the lateral direction but also for the vertical direction of a solar cell²¹. Other studies clarified the heterojunction domain interface and the domain-dependent surface potential^{22–31}, while the domain interface potential has not been well investigated.

The present study reveals phenomena of the lateral contact potential difference (V_{CPD}) distribution at a greater than 1 μm scale based on the heterojunction arrangements. We focus on studying *p*–*n* junctions using two terraced-bilayer (TB) structures consisting of a well-known and typical combination as the photovoltaic³⁹ materials, namely, PTCBI and H_2Pc on an ITO substrate [PTCBI = 3,4,9,10-perylenetetracarboxylic-bisbenzimidazole (*n*-type); H_2Pc = 29H,31H-phthalocyanine (*p*-type); indium tin oxide (ITO)]. The combination of phthalocyanine and PTCBI was the first organic photovoltaic *p*–*n* junction^{1,10–12} and is stable for photoelectrochemical^{40–44} and photocatalysis^{14,15} processes. Typically, each of the PTCBI and H_2Pc layers had a *ca.* 50 nm thickness. As shown in Scheme 1, the two TB samples were in the form of (top layer)/(bottom layer)/ITO. TB- H_2Pc /PTCBI/ITO and TB-PTCBI/ H_2Pc /ITO denote each of the terraced bilayer samples. The TB samples have a single layer region (SLR), a bilayer region (BLR), and a boundary region (BDR).

In the present SKPM study, we have obtained distinctive lateral V_{CPD} characteristics at the BDR of TB- H_2Pc /PTCBI/ITO and TB-PTCBI/ H_2Pc /ITO. The lateral distribution of V_{CPD} had a positive peak for the case of *p*-type on *n*-type structures (i.e., TB- H_2Pc /PTCBI/ITO) and a gradient for the case of the *n*-type on *p*-type structure (i.e., TB-PTCBI/ H_2Pc /ITO). These two characteristics were also shown in the case of the other *p*–*n* combinations of H_2Pc and fullerene C_{60} (i.e., TB- H_2Pc / C_{60} /ITO and TB- C_{60} / H_2Pc /ITO). Based on these observations, we designed terrace dot electrodes and prepared one using vapor deposition with a mask. Using such an electrode, a more negative threshold potential of the photoanodic current was observed. We also utilized the

positive potential as an enhanced oxidation power in a photocatalyst application by using the same molecule, based on micrometer geometry control.

Experimental methods

Sample preparation

The ITO glasses (sheet resistance $\leq 15 \Omega/\text{sq}$; transmittance $> 85\%$; ITO thickness = 150 nm; Kuramoto Co., Ltd., Tokyo, Japan.) were cut into a 3 cm \times 1 cm size and cleaned using ultrasonication with acetone and then ethanol. PTCBI was synthesized⁴⁵ and purified according to a previously described procedure⁴⁶. The sublimation of PTCBI was performed in a tubular furnace (ATF350-AST3), custom made by Alpha Giken Co. H_2Pc (Tokyo Chemical Industry Co. Ltd.) is commercially available and was purified by sublimation prior to use⁴⁶. C_{60} (Tokyo Chemical Industry Co. Ltd.) was used as received. PTCBI, H_2Pc and C_{60} were individually vapor deposited (using a ULVAC VPC-250) to a *ca.* 50 nm thickness at a speed of 0.010–0.020 nm/s and were monitored with a quartz crystal microbalance (QCM) device. Terraced-bilayer samples of TB- H_2Pc /PTCBI/ITO and TB-PTCBI/ H_2Pc /ITO were prepared by depositing the second (top) layer of material using a paper mask (RMS edge roughness was *ca.* 7 μm) covering approximately half of the first (bottom) layer area. For the photoelectrochemical study, the bilayer electrode was prepared using vapor deposition as previously described. For the dot pattern terrace bilayer electrode, a shadow mask (nickel, diameter = 200 μm , pitch = 400 μm , 8 \times 8 dots, line-edge roughness = 1 μm) was used for the deposition of H_2Pc on PTCBI. The active area of the electrode was fixed to be 3 mm \times 3 mm. For the photocatalyst film preparation (H_2Pc (50 nm)/PTCBI (50 nm)/PTFE membrane), commercially available PTFE membrane filters (MILLIPORE, JMWP01300, pore size =

5 μm and thickness = 80 μm) were used as the substrate for the deposition of the bilayer and dot terrace bilayer structure.

Surface potential measurement

Samples were measured in the ambient condition using an Asylum Cypher S for atomic force microscopy (AFM) with a controller to stabilize the environment temperature. The operation mode for the SKPM measurement was based on the amplitude modulation (AM) mode⁴⁷. Non-contact mode cantilevers (OCML-AC240TM, OLYMPUS) were used with a typical resonant frequency and a spring constant of approximately 70 kHz and 2 N/m, respectively. The tip-sample distance and the applied AC voltage were set to 50 nm and 3 V, respectively. The SKPM images and sectional analysis (Scheme S1) were obtained and processed using a procedure implemented in Igor Pro (Wavemetrics), which is an AFM software controller. The scanning locations of the BLR and the SLR were set at a lateral distance of at least ca. 3–5 mm from their respective BDR. For the measurement at the BDR, the tip was positioned between the BLR and SLRs within the maximum 30 μm size scan area available in our AFM.

A halogen light source (Megalight 100, SCHOTT) was used for irradiation with white light. The light intensity was ca. 9 mW/cm^2 .

Photoemission spectroscopy

To measure the ionization potential (HOMO) of an organic semiconductor, photoemission yield spectroscopy in air (PYSA) was performed using a Riken Keiki AC-3 (photon energy: 4.0 ~ 6.2 eV, photon power: 740 W). A Riken Keiki AC-2 (photon energy: 3.4–6.2 eV, photon power: 500 nW) was used to perform PYSA to measure the work function of the ITO and Au/Cr substrates.

Photoelectrochemistry

The electrochemistry measurement was performed in the dark and under the illumination (70 mW/cm^2) of a halogen lamp (Megalight 100, SCHOTT) whose spectrum of the white light has been shown elsewhere¹⁴ and under the illumination of a solar simulator (PECCELL PEC-L15) with an intensity of 100 mW/cm^2 . The electrolyte was 10 mM 2-mercaptoethanol in KOH (pH: 11) unless a different concentration is mentioned in the figure caption. The scan rate was 0.5 mV/sec unless otherwise stated in the figure caption. A Pt electrode was used as the counter electrode. The reference electrode was a Ag/AgCl (in saturated KCl electrolyte) electrode.

Photocatalysis

In the photocatalysis study, LED ring lights (PROFO-TONIX) with $\lambda = 630$ nm were used as a light source. The fabricated photocatalyst films (i.e., H₂Pc/PTCBI/PTFE

membrane filter) were individually kept in 1 ml of a 3 wt% aqueous solution of acetic acid in a gas chromatography-type vial (size 1.5 ml) and irradiated for 1 h with a light intensity of 1 mW/cm^2 . The photocatalytic performance was evaluated using the CO₂ generation. The concentration of CO₂ generation was monitored using gas chromatography (Shimadzu GC 2014) for vials with and without the presence of a H₂Pc/PTCBI/PTFE membrane filter. The external quantum efficiency of CO₂ generation (EQE_{CO_2}) was calculated using:

$$EQE(\%) = nN_A M \times 100 / IAt, \quad (1)$$

where n is the number of positive holes needed to produce a CO₂ molecule, N_A is Avogadro's number (particles mol^{-1}), M is the amount of CO₂ generated (in mol), I is the incident photon flux (in photons $\text{cm}^{-2} \text{s}^{-1}$), A is the area of the photocatalyst film (in cm^2), and t is the irradiation time (in s).

Results and discussion

Contact potential difference (V_{CPD}) analysis of substrates

First, the electrical connection was confirmed, using an independent measurement of the potential difference between the substrates and the electrical ground terminal of the SKPM system, to be ca. 0 V (<0.1 mV). Next, V_{CPD} (in V) was measured for the ITO-coated glass and the Au-coated Cr electrode, which are conducting substrates without the deposited OSMs. Some of the V_{CPD} mappings are shown in Figure S1 for a 30 $\mu\text{m} \times 3 \mu\text{m}$ area, and the average values are summarized in Table 1. The V_{CPD}

values were 0.05 V and $-0.08\sim 0.22$ V for Au on Cr and ITO, respectively, with a sample-dependent error of ± 35 mV and ± 150 mV. The V_{CPD} value is the bias potential between the probe (ϕ_{probe}) and the sample (ϕ_{sample}) when the coulomb interaction is nullified between them⁴⁷.

$$V_{CPD} = (\phi_{probe} - \phi_{sample})/e \quad (2)$$

For the conductive sample, the ϕ_{sample} value (in eV) should equal the work function (E_F in eV). According to previous studies, $\phi_{probe} = 4.92^{48}\sim 5.6^{49}$ [eV] for Pt-coated Ir, and here, we adopt $\phi_{probe} = 4.92$ [eV]. Then, ϕ_{ITO} and $\phi_{Au/Cr}$ were estimated to be 4.81 and 4.98 eV, which are slightly deeper than the work functions of 4.20–4.78 eV (chemically washed ITO)^{50–53} and 4.79 eV (Au), respectively, as shown in Table 1. There have been discussions about the pretreatment effect of ϕ_{ITO} ^{50–53}, where oxygen plasma cleaning induced a positive shift to $\phi_{ITO} > 5.02$ eV^{50–52} and a return to $\phi_{ITO} \sim 5.02$ eV upon exposure to air⁵¹. The present sample difference in ϕ_{ITO} is within the difference discussed in the previous papers.

Contact potential difference (V_{CPD}) analysis in the single layer films PTCBI/ITO and H₂Pc/ITO

Single layer films on ITO, i.e., PTCBI/ITO and H₂Pc/ITO, were individually prepared, and the contact potential difference was obtained together with topographic images (Figures S2 and S3, respectively). The mean surface roughness of PTCBI was *ca.* ± 5 nm, while that of H₂Pc was *ca.* ± 10 nm. From the map, a scan line of the contact potential difference was obtained as the average of the rectangular direction (256 pixels) and is shown in Figure S4. The total average contact potential difference on the line was 0.28 and 0.17 V for PTCBI/ITO and H₂Pc/ITO, respectively, under the dark condition.

In this work, the error for the samples was *ca.* ± 10 mV, as seen in the lines in Figure S4. Generally, for the SKPM measurement, a source of error was the sample-tip probe capacitance due to the geometrical effect of the tip apex⁵⁴. The tip dependence was within the error for the sample above, as shown in Figure S5, where a sample was measured using two different tips of the cantilever. However, the sample dependence of V_{CPD} was larger than the tip dependence, as shown in Figure S6, for the same type of sample series. Interestingly, the difference in the V_{CPD} of the sample from that of the substrate did not depend on the samples within the error of ± 0.1 V. In this study, we chose ITO having $0.1 \text{ V} < V_{CPD} < 0.2 \text{ V}$.

From Eq. (2), the ϕ_{sample} value of the OSM was estimated to be 4.60 eV for H₂Pc/Au and 4.75 eV for PTCBI/Au, as shown in Table 1. These ϕ_{sample} values approximately agreed with the previous reports of 4.44 eV for H₂Pc/Au⁵¹ and 4.9 eV for PTCBI/Au³⁴.

In previous studies on phthalocyanines⁵⁵ and PTCBI⁵⁶ using UPS, the E_F depended on the substrate material, such as a metal or ITO, and was ascribed to more than the factors in the conventional Mott-Schottky model: (1) The Fermi levels were unaligned at the substrate/OSM junction. The nonalignment was discussed in connection with the incorporation of O₂ and/or H₂O into the OSM³². (2) The metal-OSM charge transfer and formation of polaron-like states at the OSM-substrate interface affected the vacuum level shift.

Using PYSA, the HOMO levels were estimated and are shown in Table 1. When these values were compared with the ϕ_{sample} values for H₂Pc, the latter were *ca.* 0.5 ~ 0.8 eV shallower than the HOMO level, while PTCBI exhibited a level that was *ca.* 1.3 ~ 1.4 eV shallower than the LUMO level. When ϕ_{sample} is treated as the E_F of the OSM, the difference would agree with the *p* and *n* character of H₂Pc and PTCBI, respectively, for the ambient condition.

Figure 1 shows the electronic energy level for each of the single layer OSMs on ITO. There is a clear shift of ϕ_{sample} for PTCBI/ITO and H₂Pc/ITO, suggesting that the vacuum level shift is 0.24–0.25 eV³². For the OSMs, a thickness dependence of ϕ_{sample} was observed for both PTCBI/ITO and H₂Pc/ITO. The PYSA data for the thickness-dependent samples indicated that the HOMO level of H₂Pc/ITO shifted, while that of PTCBI/ITO did not.

Under illumination, V_{CPD} shifted for PTCBI/ITO (20 mV), while that for H₂Pc/ITO only slightly shifted (-10 mV), as shown in Figure S4. Itoh et al. found a similar slight positive shift for C₆₀/ITO and no change for CuPc/ITO under light illumination. The difference between the *p*- and *n*-type characters might induce the shift of V_{CPD} by light-induced electron transfer from the OSM to ITO³⁷.

Contact potential difference (V_{CPD}) analysis in a SLR of the TB samples

From here, we discuss the V_{CPD} characteristics in the terraced-bilayer (TB) structure. Scan lines of V_{CPD} are shown in Fig. 2 for both TB-H₂Pc/PTCBI/ITO and TB-PTCBI/H₂Pc/ITO, in which the region consisted of either PTCBI (50 nm) or H₂Pc (50 nm) on the ITO substrate. For each of the SLRs (Fig. 2a, b, SLR), the V_{CPD} value of TB-H₂Pc/PTCBI/ITO (0.40 V) was more positive than that of TB-PTCBI/H₂Pc/ITO (0.24 V), similar to those of the simple single layer samples (Figure S4).

Contact potential difference (V_{CPD}) analysis in the BLR of the TB samples

Figure 2c, d show the 128 pixel-averaged V_{CPD} for parts of each BLR of TB-H₂Pc/PTCBI/ITO and TB-PTCBI/H₂Pc/ITO, respectively, and the V_{CPD} values are 0.54 V and -0.02 V. The ϕ_{sample} values were estimated using Eq. (2) as $\phi_{H_2Pc/PTCBI} = 4.38$ eV and $\phi_{PTCBI/H_2Pc} = 4.94$ eV.

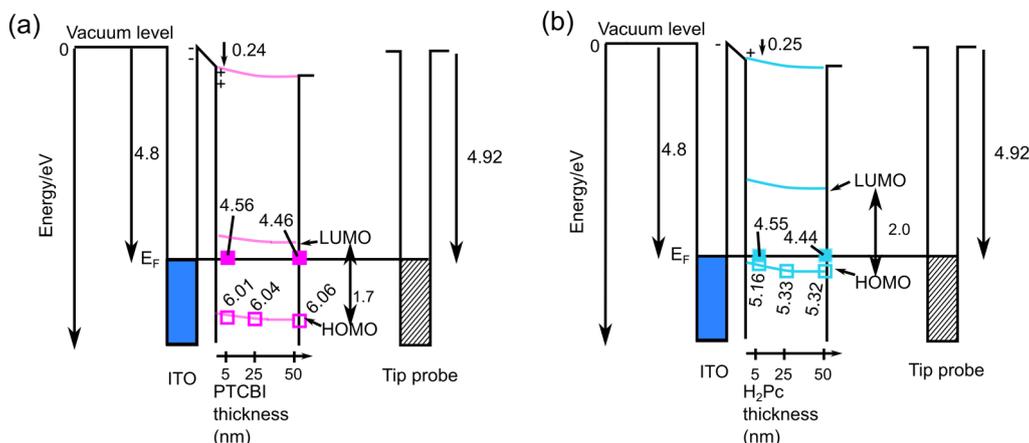

Fig. 1 Electronic structure for PTCBI/ITO and H₂Pc/ITO with the HOMO level observed using PYSA and the ϕ_{sample} values in the dark. At the ITO/OSM interface, a vacuum level shift was assumed based on the difference between ϕ_{sample} and ϕ_{ITO}

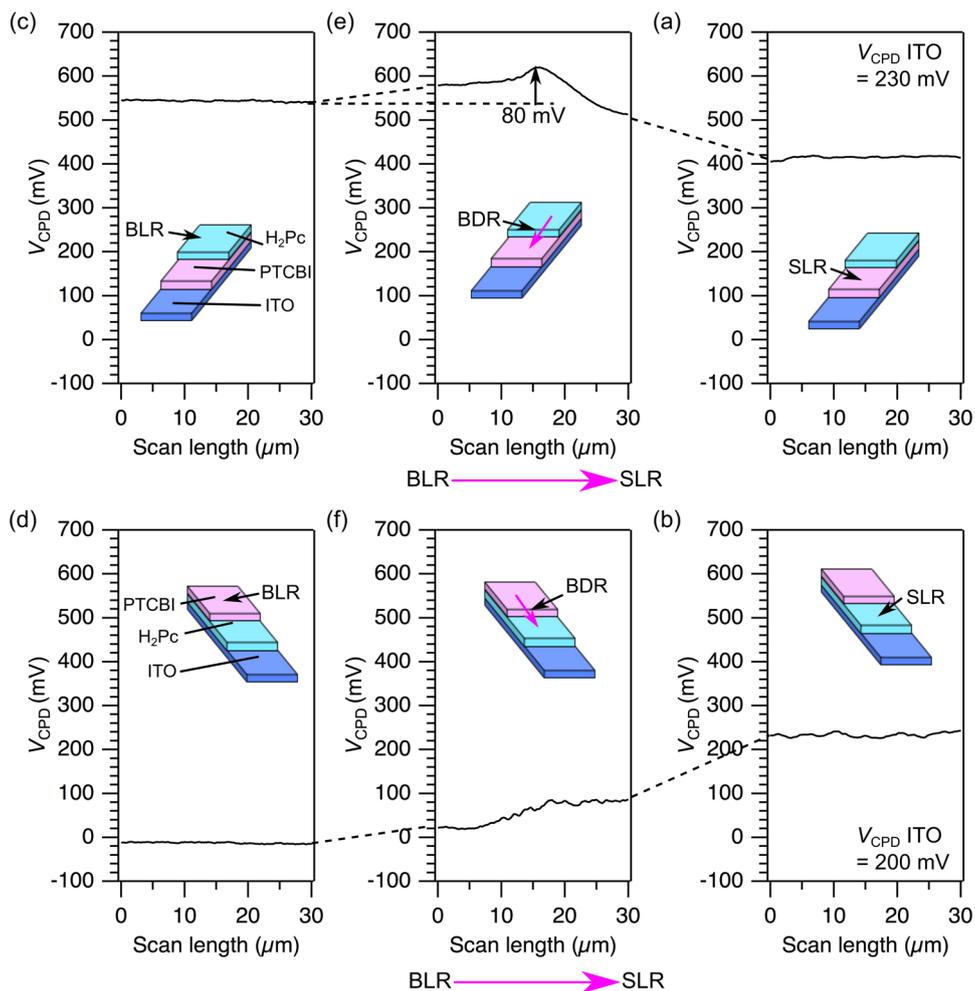

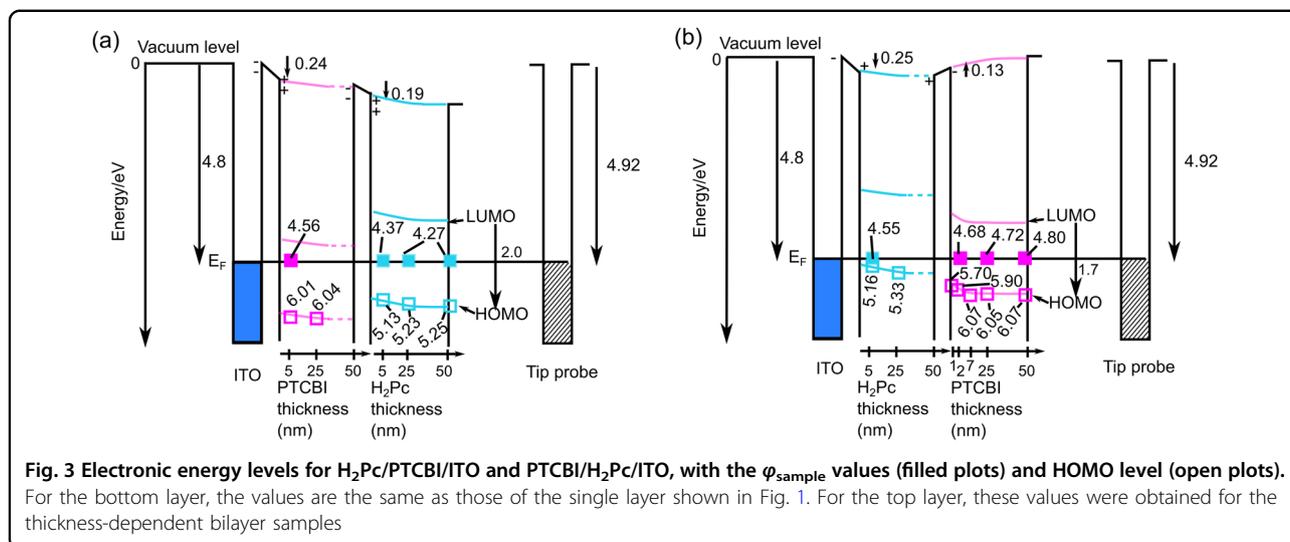

Fig. 2 Lateral V_{CPD} in TB-H₂Pc/PTCBI/ITO and TB-PTCBI/H₂Pc/ITO under the dark condition. **a, b** single layer region (SLR), **c, d** bilayer region (BLR) and **e, f** boundary region (BDR). Purple arrows at the bottom in **(e, f)** indicate the directions of the BLR to the SLR. The scanning locations of the SLR and BLR were set at a lateral distance of at least ca. 3–5 μm from their BDR, and the detailed distance is shown in Fig. 5. The vertical arrow in **(e)** indicates the amplification in the BDR (ca. 80 mV)

These V_{CPD} and ϕ_{sample} values are very different from those of single layers and imply an effect on the OSM as a substrate. Notably, the differences of the ϕ_{sample} values between the single and BLRs are coincidentally 0.2 V for both cases; i.e.,

$$\phi_{\text{H}_2\text{Pc}/\text{PTCBI}} - \phi_{\text{PTCBI}} \approx -0.2[\text{eV}] \quad (3)$$

$$\phi_{\text{PTCBI}/\text{H}_2\text{Pc}} - \phi_{\text{H}_2\text{Pc}} \approx 0.2[\text{eV}] \quad (4)$$

The above difference appears consistent with the same potential shift at the H₂Pc/PTCBI interface. Here, again, we have prepared a series of thickness-dependent samples for the top layer and measured them using both PYSA and SKPM. The data are shown in Fig. 3. The plots of the HOMO level are obtained using the PYSA experiments for the thickness-dependent bilayers. Because the surface of the bottom layer in the BLR is not exposed to air, the plots are not shown for the bottom layer at the $p-n$ junction, and the energy levels are drawn as dotted lines. Based on Eq. (2), ϕ_{sample} can be estimated, as shown in the filled plots. For H₂Pc on PTCBI, i.e., the top layer, $\phi_{\text{H}_2\text{Pc}/\text{PTCBI}}$ was much shallower than that in the single layer, $\phi_{\text{H}_2\text{Pc}}$, while for PTCBI on H₂Pc, $\phi_{\text{PTCBI}/\text{H}_2\text{Pc}}$ was deeper than that of ϕ_{PTCBI} . These shifts are consistent with electron transfer from p-type to n-type. For the top layer, both the PYSA and SKPM measurements indicated band bending for the cases of both H₂Pc/PTCBI/ITO and PTCBI/H₂Pc/ITO. Interestingly, the observation of the vacuum level shift was not consistent for the two bilayer samples, i.e., from PTCBI to H₂Pc for H₂Pc/PTCBI/ITO and from H₂Pc to PTCBI for PTCBI/H₂Pc/ITO. Similar asymmetric phenomena were reported in C₆₀/H₂Pc/Au and H₂Pc/C₆₀/Au by Ishii et al.³⁸

Such a description is not simplified as described in Eqs. (3) and (4), as is apparent from the ϕ_{PTCBI} for the 50 nm

top layer. At the $p-n$ junction, the vacuum level shift from p-type to n-type can be drawn if we assume a flat energy level for the bottom layer, such as the dotted line shown in Fig. 3, even in the dark.

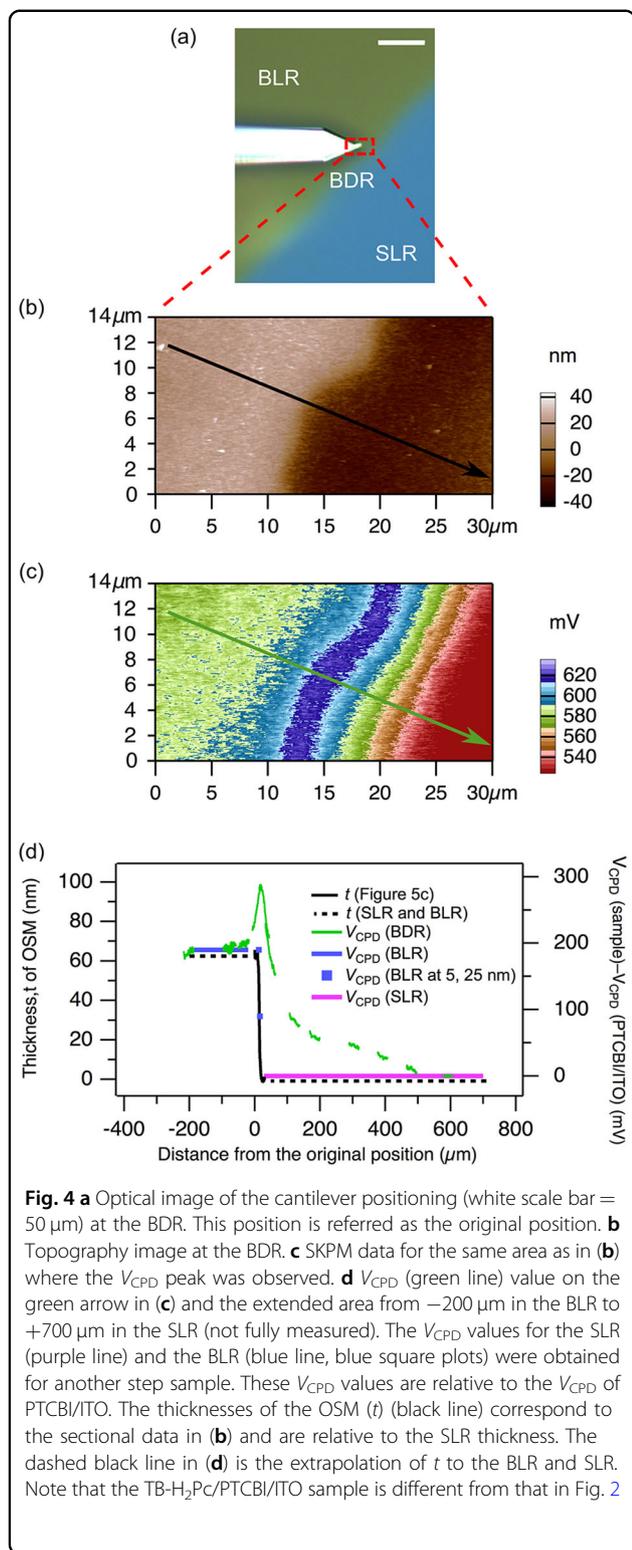

From a separate experiment, Figures S7c and d show the data taken under illumination, where V_{CPD} of the BLR shifted to a deep level for TB-H₂Pc/PTCBI/ITO, while it shifted little for TB-PTCBI/H₂Pc/ITO. In the cases of the single layer, PTCBI/ITO showed a shift, while H₂Pc/ITO did not (Figure S4). The difference between the bilayers is due to a similar reason as for the electron transfer from the OSM to ITO seen in the SLR.

Contact potential difference (V_{CPD}) in the BDR of the TB samples

Figure 2e shows a positive peak of the V_{CPD} value in the BDR of TB-H₂Pc/PTCBI/ITO. V_{CPD} was continuous from the far SLR to the far BLR, as shown in Fig. 4d (green line). The amplification in the BDR (0.62 V) from the BLR (0.54 V) was +0.08 V, i.e., $0.62 - 0.54 = +0.08$ V, under the dark condition. The BDR of TB-PTCBI/H₂Pc/ITO (Fig. 2f) showed no amplification.

As shown in Figure S7e (red line), under illumination, the V_{CPD} characteristics at the BDR of TB-H₂Pc/PTCBI/ITO showed a positive peak similar to that in the dark and had a shift to a more positive potential. For the BDR of TB-PTCBI/H₂Pc/ITO, as shown in Figure S7f (red line), the V_{CPD} shift at the BDR was small. Such a bottom layer dependence was similar for the cases of the SLR and BLR.

In the case of the Au/Cr substrate, V_{CPD} had a similar peak, as shown in Figure S8, which supports that the present peak is due to the $p-n$ junction not the substrate, such as ITO or Au. On the other hand, the ϕ_{sample} values for a single layer on Au/Cr were different from the cases with an ITO substrate, while the apparent relation shown

in Eqs. (3) and (4) was observed for both TB- H_2Pc /PTCBI/Au/Cr and TB-PTCBI/ H_2Pc /Au/Cr in the dark, as well as when they were illuminated.

To investigate these V_{CPD} characteristics at the BDR for another combination of the p - n junction in the TB samples, TB- H_2Pc / C_{60} /ITO and TB- C_{60} / H_2Pc /ITO (C_{60} = fullerene molecule, n -type) were fabricated. The SKPM measurement (in Figure S9) showed that the BDR of TB- H_2Pc / C_{60} /ITO and TB- C_{60} / H_2Pc /ITO also had the lateral distribution of V_{CPD} of a positive peak and gradient characteristics, respectively, for their structures of TB- p -type/ n -type/ITO and TB- n -type/ p -type/ITO. These data showed that the peak is due to the terrace bilayer structure with p -type on n -type.

Figure 4a shows an optical image of the cantilever placed in proximity to the BDR between the SLR and the BLR of the TB sample. The structure of the cantilever was that the tip of the probe was located at the exact end of the cantilever so that the tip was easily positioned. Figure 4b, c show the topography and V_{CPD} mapping, respectively, in the BDR of TB- H_2Pc /PTCBI/ITO.

The maximum V_{CPD} value (~ 620 mV) spanned the boundary (Fig. 4d). Generally, when discussing the V_{CPD} value, we must treat it is a weighted average of a certain region below the tip due to the finite tip size. The spatial resolution of SKPM is lower than that of AFM due to the difference between the long-range electrostatic force and the short-range van der Waals force. This problem is discussed by Sadewasser et al. in detail, especially for groove structures and step structures⁵⁴, the latter of which is the same as the present topic. According to the study, the peak height of the signal of the V_{CPD} value was $\sim 60\%$ of the input V_{CPD} value, with broadening of the FWHM being linear against the input space charge region of $50 \sim 200$ nm with 100 meV of contact potential difference for the 50 nm tip-sample distance. Additionally, for the step substrate, broadening of the contact potential difference more than that of topography was simulated, with a < 10 nm shift (output of the simulation) of the step border area to the lower step area for a 5 nm tip-sample distance (input of the simulation). Then, in this present study, by assuming the linearity between the potential and the tip-sample distance (50 nm), the broadening of the spatial resolution might be 50 nm, which is less than the width of the spatial resolution for the potential peak observed here ($\sim 10 \mu\text{m}$ in Figs. 2e and 4d). This means that the $10 \mu\text{m}$ width of the peak is not an artificial error.

The topographical step may affect the local V_{CPD} as a real and/or artifactual peak. The present step has a slope. To evaluate the effect, a control TB- H_2Pc / H_2Pc /ITO homo junction terrace bilayer sample was prepared independently, and both the topography and V_{CPD} value (Figure S10) were measured. The V_{CPD} data of Figure S10, C3 and D3 show that there were no V_{CPD} peaks, irrespective of the slope steepness, and show that the V_{CPD} peak observed in Fig. 2e, c was due to the terrace bilayer

structure with *p*-type on *n*-type. This fact means that the present peak is not an artifact due to the step structure.

Moreover, to investigate whether the peak is or is not due to the steep step morphology, another control sample was fabricated to be a planar *p*-*n* junction with small angle crossing of H₂Pc and PTCBI. As shown in Figure S11, the topography and the SKPM data were measured along the single layer PTCBI to the single layer H₂Pc. The data (for Figure S11, b and e, black filled circle) show that there was a V_{CPD} peak that reached 650 mV near the flat area (i.e., planar *p*-*n* structure). This demonstrates that a V_{CPD} peak can also occur in a planar *p*-*n* structure and is not due to the steep morphology.

There have been reports of applying SKPM for the study of the peak V_{CPD} at the edge of an OSM crystal^{21,57}. Sadewasser et al. simulated the peak V_{CPD} using a model of the space charge region⁵⁴, for which the width and carrier concentration determine the peak potential value and width observed. The observed peak values were simulated to be approximately half (40–60 mV) of the real potential value (100 mV).

In a typical photovoltaic device, the *p*-*n* junction direction is normal to the two electrodes, and then, the potential changes to the normal direction due to the space charge region, surface dipoles, etc. In such a case, the potential difference should be observed as being thickness dependent. We try to interpret the V_{CPD} in the BDR of TB-H₂Pc/PTCBI/ITO as a thickness-dependent V_{CPD} . In Fig. 4d, the topography at the BDR is shown, and the thickness of H₂Pc is from zero to 50 nm. The thickness-dependent V_{CPD} values are the purple-filled plots, which also do not have a peak and are different from the V_{CPD} in the BDR (Fig. 4d, green solid line). In comparison, it is impossible to interpret the V_{CPD} peak at the BDR as a thickness-dependent V_{CPD} due to the normal direction of the potential changing based on the lateral component of the *p*-*n* junction on the substrate.

Considering these results, a reasonable interpretation is that the V_{CPD} peak originates from the localization of positive charges due to the lateral component of the *p*-*n* junction, where the charge transfer occurs not only in the substrate's normal direction but also in the lateral direction. As a result of such a lateral polarization, a positive peak might occur in the BDR, as shown in Fig. 5.

If the potential maximum at the BDR is real, then the potential maximum would give a favorable oxidation power. In a practical application, the greatest output is desired. Additionally, not only a positive V_{CPD} peak but also a considerable quantum efficiency, typically IPCE, defined as the current per incident light, is required. To confirm the lateral potential maximum effect, we have prepared electrodes with more terraces and more BDRs using vapor deposition with a mask, as shown in Figure S12. The positive V_{CPD} peak lay within the

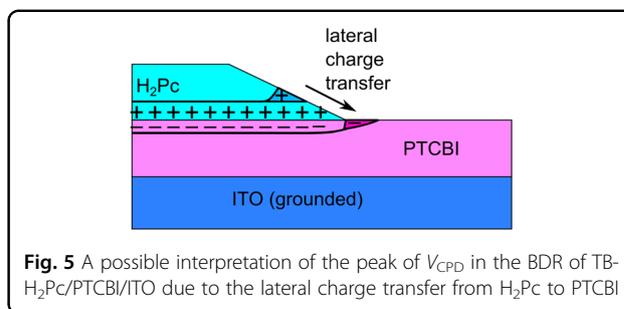

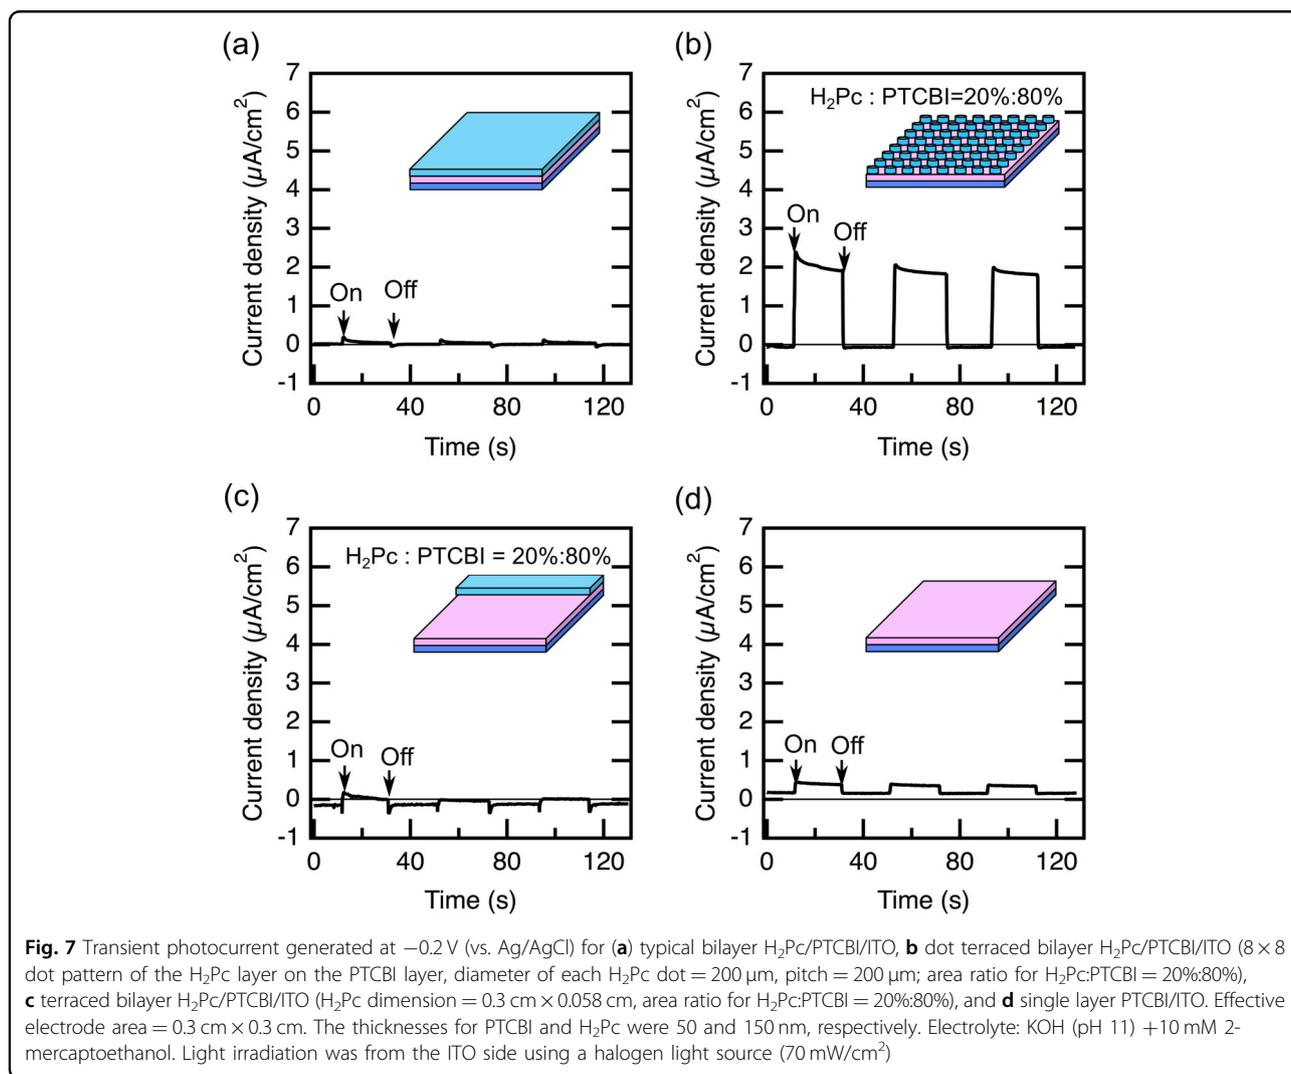

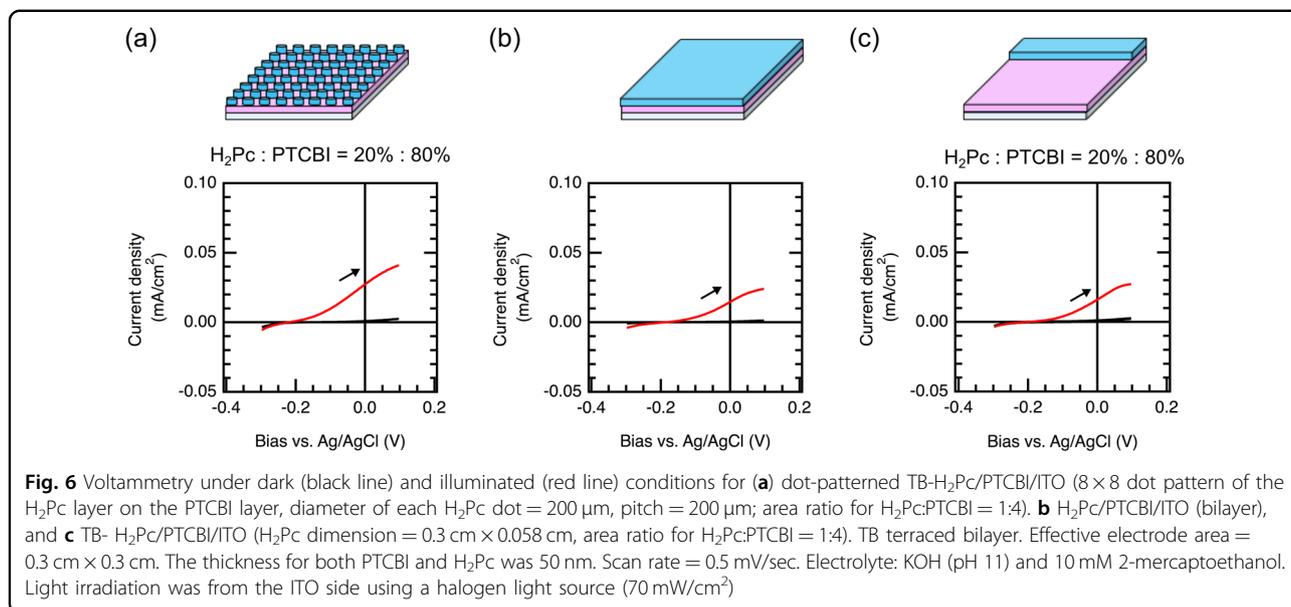

Fig. 5 A possible interpretation of the peak of V_{CPD} in the BDR of TB-H₂Pc/PTCBI/ITO due to the lateral charge transfer from H₂Pc to PTCBI

micrometer-wide BDR, as expected based on the previous discussion. In addition to the V_{CPD} measurement, we performed PYSA experiments and obtained a more positive ionization potential value of 5.27 eV.

Figure 6a shows the *I*-*V* curve of an electrode designed with more BDRs and prepared using vapor deposition with the mask. The new electrode was compared with the simple bilayer electrode (Fig. 6b) and the terrace bilayer with a controlled area ratio between PTCBI/H₂Pc BLR (~20%) and PTCBI SLR (~80%) (Fig. 6c). In the absence of incident light, no current was observed, while a photoanodic current was observed for all of the cases shown in Fig. 6. The trend was the same as in previous studies, i.e., photoelectrochemical oxidation of thiol occurred under illumination, while no conduction occurred in the dark⁴⁰. The designed and patterned electrode exhibited a more negative threshold potential (~-0.2 V, seen in Fig. 6a, red) for the photoanodic current. The threshold potential was ~0.1 V less positive than those for the conventional bilayer and terraced bilayer (~-0.1 V, seen in Fig. 6b, c, red). Figure 7 shows the light on/off response at the bias potential of -0.2 V vs. Ag/AgCl, which is at the threshold potential of the dot terrace bilayer electrode. Among these electrodes, only the design-patterned electrode exhibited a photoanodic current. In a separate experiment, the bilayer and the dot terrace electrodes were tested under a solar simulator (intensity = 1 sun or 100 mW/cm²), with double the concentration of donor molecule (20 mmol dm⁻³) and at the bias potential of +0.1 V vs. Ag/AgCl. Figure S13 shows that the photocurrent of the dot terrace electrode was enhanced by ~30 μA/cm² compared with that of the bilayer.

From these results, it was confirmed that the positive V_{CPD} peak at the BDR can be utilized for macroscopic photoanodic current generation with a lower negative bias potential.

Figure 8 shows the action spectra of the photoanodic current at 0 V vs. Ag/AgCl. At such a small bias potential, the IPCE is at a small < 1% level, while the dot sample shows a value of ~4%. In addition to the greater external quantum efficiency for the design-patterned electrode, the shape of the spectrum is different from that for the conventional bilayer. The results of the control experiment of

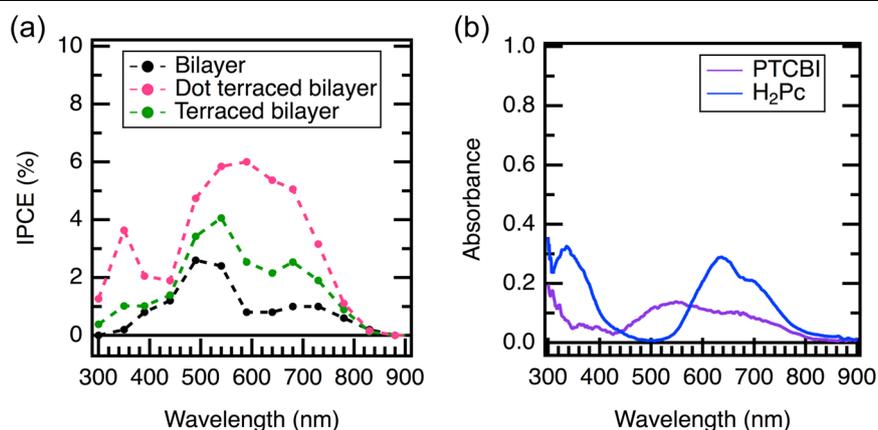

Fig. 8 a Action spectrum at 0 V vs. Ag/AgCl for the typical bilayer H₂Pc/PTCBI/ITO (black), dot terraced bilayer H₂Pc/PTCBI/ITO (red) (8 × 8 dot patterns of the H₂Pc layer on the PTCBI layer, diameter of each H₂Pc dot = 200 μm, pitch = 200 μm; area ratio for H₂Pc:PTCBI = 20%:80%), and terraced bilayer H₂Pc/PTCBI/ITO (green) (H₂Pc dimension = 0.3 cm × 0.058 cm, area ratio for H₂Pc:PTCBI = 20%:80%). Effective electrode area = 0.3 cm × 0.3 cm. The thicknesses for the PTCBI and H₂Pc were 50 nm and 150 nm, respectively. Light source wavelength: 300–900 nm, photon flux = 10¹⁶ cm⁻¹ s. Electrolyte: KOH (pH 11) + 10 mM 2-mercaptoethanol. Light irradiation was from the H₂Pc side. **b** Absorbance spectrum for PTCBI (50 nm) and H₂Pc (50 nm)

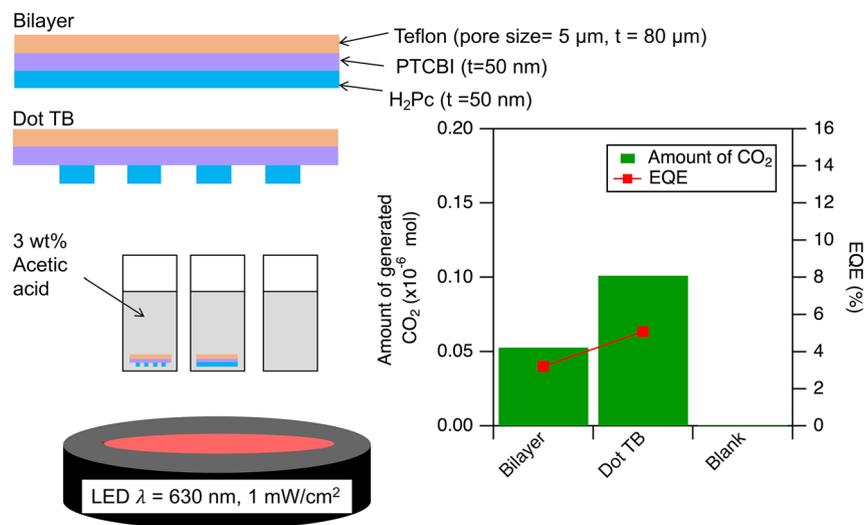

Fig. 9 Scheme for the experimental setup of the bilayer and dot terrace bilayer film photocatalyst to decompose 3 wt% aqueous solution of acetic acid into CO₂ under monochromatic light irradiation (λ = 630 nm, intensity = 1 mW/cm²). The dot terraced bilayer H₂Pc/PTCBI/Teflon membrane was prepared with a diameter of each H₂Pc dot = 200 μm, pitch = 200 μm. Membrane size ≈ 0.6 cm × 0.6 cm. The thickness of both the PTCBI and H₂Pc was 50 nm. The control sample was a container without any film that was kept under the dark condition. Light irradiation was from the H₂Pc side. The irradiation time was 1 h. The result from the gas chromatography analysis is shown for the amount of CO₂ evolution (in mol) and EQE (in %). The amount of CO₂ in the blank sample was 0.02 μmol, and the value was zeroed to be the baseline value for the bilayer and the dot TB samples

the simple terrace sample were between those of the above two electrodes in terms of the EQE and spectral shape. The spectrum shape of the bilayer with a filter effect through H₂Pc due to considerable quenching of the exciton of H₂Pc was previously investigated⁴⁰. For the present shape, the relatively higher EQE for ~600 nm is due to less of a filtering effect due to the lack of full coverage by the H₂Pc layer. This phenomenon also has

the merit of enhancing the photoanodic current in addition to the effect on the BDR positive V_{CPD} peak.

To test the effect of the more positive potential in the BDR for an application, we fabricated H₂Pc(50 nm)/PTCBI(50 nm) on a PTFE membrane filter (80 μm) as the bilayer and dot terrace bilayer (Fig. 9) to investigate the photocatalytic performance in decomposing acetic acid under visible light irradiation (λ = 630 nm, intensity = 1

mW/cm²). The control sample was a container without any film (i.e., a blank sample) that was kept under the dark condition. From the gas chromatography analysis, the dot terrace bilayer photocatalyst exhibited a higher performance than did the bilayer photocatalyst for the decomposition of acetic acid into CO₂ gas. By assuming the following chemical equation:

the quantum efficiency, EQE (%) (as in Eq. (1) and using $n = 4$) was estimated to be 5.1% for the dot terrace bilayer sample and 3.2% for the bilayer sample. This result demonstrates that a more positive potential at the BDR can enhance the photocatalytic performance by enhancing the oxidation power.

Conclusions

This paper described the lateral V_{CPD} characteristic at the BDR for the terrace bilayer electrode of n -type PTCBI and p -type H₂Pc and a comparison of the SLR and BLR. The analysis of the V_{CPD} values of the SLRs and BLRs was consistent with the electron transfer and vacuum level shift at the interfaces through the Fermi level alignment that occurs from the OSM into the ITO. For the BLRs, a 0.2-V shift of V_{CPD} in the 50 nm top layer was observed, and the thickness-dependent V_{CPD} gave a more complicated energy level shift at the p - n junction and band bending. For the BDR, there was a positive peak of V_{CPD} (+0.1 mV for the BLR) for TB-H₂Pc/PTCBI/ITO, while for TB-PTCBI/H₂Pc/ITO, there was a broad and small peak of V_{CPD} . The V_{CPD} peak is not an artifact, and the real value should be more than adequately observed due to the experimental resolution limitation. The V_{CPD} peak was impossible to interpret from the thickness-dependent V_{CPD} values. We may interpret it as a lateral direction charge separation. An enhanced oxidation power was confirmed by the use of a dot terrace electrode through photoelectrochemical observations at a smaller bias and with a lower filter effect from the H₂Pc absorption. Moreover, the more positive potential at the BDR led to a high performance in the photocatalyst film for the decomposition of organic compounds. The enhancement of the oxidation power was experimentally proven to be a new design for a universal additional p - n junction-type photocatalyst without changing the molecular component.
